

DESIGN OF PUBLIC PROCUREMENT AUCTIONS: EVIDENCE FROM CLEANING CONTRACTS

Ari Hyytinen, Sofia Lundberg and Otto Toivanen *

This draft version:

November 26, 2017

Abstract

We analyze a regime change from beauty contests to first-price sealed-bid and scoring auctions, using Swedish data on public procurement of cleaning services. In beauty contests, the lowest bid often lost, leaving substantial money on the table. The procurement costs were similar before and after the regime change: i) Entry strongly decreases the procurement cost, but did not change. Entry would have decreased had the municipalities not adjusted the objects of auctions. ii) Municipalities favored inhouse suppliers in the old regime, leading to more aggressive bidding by others. With favoritism reduced, these changes balanced each other out.

KEYWORDS: public procurement, auction design, entry, beauty contests, scoring

Sofia Lundberg: Department of Economics, Umeå School of Business and Economics at Umeå University; sofia.lundberg@umu.se. Otto Toivanen: Aalto University School of Business and KU Leuven; Otto.Toivanen@aalto.fi. This article supersedes the earlier procurement analyses of ours that circulated under various titles, such as “Favoritism in public procurement: Evidence from Sweden” and “Politics and procurement: Evidence from cleaning contracts”. Those earlier versions had a different focus and used part of the same contract data used in this article. We would like to thank a number of colleagues and seminar participants for useful comments on those earlier versions, and Marc Rysman (Editor), three anonymous referees, Rob Porter, Tuomas Takalo, Janne Tukiainen, Roope Uusitalo and seminar participants at EARIE 2016 (Lisbon) and VATT (Helsinki 2017) for comments and discussions on the current one. The usual caveat applies.

Introduction

Public procurement constitutes a large part of economic activity in developed and developing economies.ⁱ Unfortunately, inappropriate and inefficient practices are thought to be widespread in public procurement (e.g., Bandiera, Prat and Valletti, 2009; Cai, Zhang and Henderson, 2013). Recommendations for greater integrity and adoption of rule-based practices are therefore common and the benefits of using formal competitive auctions are often strongly advocated (Klemperer, 2002; Tadelis, 2012; Bajari, Houghton, & Tadelis, 2014). Though increasing buyers' discretion may be beneficial when quality is only partly contractible (e.g., Coviello, Guglielmo and Spagnolo, 2017), rule-based competitive auctions are in general believed to be less prone to inappropriate and inefficient practices. One reason for this belief is that in such auctions there are explicit criteria for selecting the winner.ⁱⁱ This article provides an analysis of the consequences of a regime change that induced a shift away from discretionary beauty contests to a more rule-based procurement environment, in which only first price sealed bid or scoring auctions were allowed.

Our data come from Swedish public procurement auctions of a clearly defined low-tech product, internal cleaning service contracts. The data cover two regimes that differ in how the law regulated public procurement. In the old regime, the Swedish procurement law allowed the municipalities exceptionally high degrees of freedom in choosing how to procure the services and in how to pick the winner.ⁱⁱⁱ The municipalities ended up using beauty contest auctions. In such an auction, the auctioneer does not commit to an award (allocation) rule (Klemperer, 2002; Yoganarasimhan, 2016). During the new regime, a much stricter procurement law was in place and the municipalities had to commit to a first price sealed

bid auction or to a scoring auction (Che, 1993; Asker & Cantillon, 2008; 2010) with an explicit award rule.

The stricter procurement law disciplined the Swedish procurement bureaucrats by forcing them to abandon the practice of using flexible beauty contests. A flipside of this change was that rule-based procurement regulation and more formal procurement processes, augmented by more detailed product requirements and bidder qualifications, may make procurement burdensome for potential bidders and thereby increase entry costs (Bandiera, Prat, and Valletti, 2009). Our primary goal is to understand what the regime change meant for municipalities' procurement costs by analyzing the determinants of winning bid and entry (participation) as well as the behavior of procurement bureaucrats, including potential favoritism.

The cleaning contracts procured by Swedish municipalities provide a good testing ground for us, because cleaning services have a very simple production process, are simple to contract on and, as we will demonstrate, do not allow significant quality differentiation *ex ante* or *ex post*. The product we study is thus much simpler and more homogenous than most of the products that have been considered in prior work. This has three implications for applicable theory: First, it is hard to believe that the Swedish municipalities could have obtained significant welfare gains by *ex ante* tilting the award rule in some non-price dimension via a scoring rule. This is in contrast to, e.g., the US highway procurements studied by Lewis and Bajari (2011). Second, *ex post* negotiations of significant adaptations to the scope of work or of cost overruns are unlikely and indeed were rare, unlike what has been found for some of the more complicated contracts and products (Bajari, Houghton, and Tadelis, 2014; Decarolis, 2013; Decarolis, 2014; Decarolis and Palumbo, 2015). Neither is there much scope for provision of non-

contractible quality (e.g., Cameron 2000; Spagnolo, 2012; Tadelis, 2012; Coviello, Guglielmo and Spagnolo, 2017). Finally, there is less uncertainty in the costs of performing the cleaning job over the duration of the contract than there is, say, in completing a major construction work (Spulber, 1990).

These considerations suggest that there should be relatively few reasons to depart from the policy of granting the contract to the lowest bidder (for a similar argument in a different context, see Di Tella and Schargrotsky 2003, Bandiera, Prat and Valletti 2009). This implies that holding other things constant, the procurement costs ought to be lower in the new regime, which only allowed the use of more rule-based and arguably more competitive first price or scoring auctions.

Despite the simplicity of the procured service, our findings portray a complex picture of the mechanisms at work. In the beauty contests of the old regime, the lowest bidder won rarely, leaving a large amount of money on the table. And yet, procurement costs did not decrease in the new regime.^{iv} We find two reasons for this: *First*, we uncover a strong inverse relation between actual entry and winning bids. Securing entry was therefore essential to competitive outcomes.^v The new regime's more rule-based procurement made auctions potentially more competitive and participation more burdensome for potential bidders. As a consequence, entry would have decreased, had the municipalities not adjusted the objects (contracts) of the procurement auctions after the regime change in a way that attracted further participation.

Second, in the old regime the Swedish municipalities were less price-sensitive and favored inhouse units, which are publicly-owned organizations of the municipalities that participated in the auctions as self-standing operative units. Although the favored bidder type was not declared in procurement documents, other bidders apparently learnt about it and reacted by bidding more aggressively

when an inhouse unit participated. This is consistent with what the prior work on favoritism (Myerson, 1981; McAfee and McMillan, 1989) and subsidies (preference programs) in auctions suggest (Marion, 2007; Krasnokutskaya and Seim, 2011; Athey, Coey, and Levin, 2013). When the scope for favoritism was reduced because of the regime change, the price sensitivity of the municipalities increased. The distribution of the (lowest) submitted bids however also changed as the other (than inhouse) bidders bid less aggressively. Had the bid distribution not changed, the shift from the beauty contests to rule-based auctions would have reduced procurement costs.

We also show that favoritism likely reflected the municipalities' willingness to sustain the viability of the inhouse units and their employment. The rule-based environment curbed this practice and decreased entry of inefficient suppliers, suggesting gains in allocative efficiency.

Our analysis is related to two strands of the literature. First, in contrast to much of the earlier literature, the beauty contests that we study were not based on an explicit price-preference rule. We therefore augment the literature which has explored how bidding and participation adjusts to changes in auction design and environment. Using data on US highway procurement auctions, Marion (2007) shows that an explicit bid preference program for small businesses increased the procurement costs a little, possibly due to reduced entry by larger, lower cost suppliers. Krasnokutskaya and Seim (2011) find that the small business preference program changed firms' incentives to participate in the highway procurement auctions. Lewis and Bajari (2011) analyze US highway and roadwork contracts and find that the procurement costs were higher in the scoring auctions, but this was counterbalanced by faster completion. Using data US timber sale auctions, Athey, Coey and Levin (2013) show that restricting entry decreases the sales revenue

(and efficiency) and that subsidizing smaller bidders would increase the revenue. Branzoli and Decarolis (2015) use data on Italian road construction and maintenance contracts to document that the use of first price auctions resulted in reduced entry and subcontracting. Decarolis (2013) shows that a switch to using first price auctions lowered the level of winning bids but did so at the cost of worse ex post performance (cost overruns, delays in completion) in Italy. Other relevant work include Cameron (2000), Eklöf (2005), Bajari, McMillan and Tadelis (2009), Athey, Levin and Seira (2011) and Coviello and Mariniello (2014). For example, Bajari, McMillan and Tadelis (2009) compare auctions and negotiations in procurement and stress tradeoffs between hard-to-observe quality and price when objects are complex and contractual design incomplete. In our case, exactly the opposite holds: Objects are simple and contractual design complete, at least when compared to the procurement of large construction projects, aircrafts and the like.

Our analysis is also related to endogenous participation and selective entry in auctions (e.g. Li and Zheng, 2009; 2012; Li and Zhang, 2010; Marmer, Shneyerov and Xu, 2013; Xu, 2013; Roberts and Sweeting, 2013; Gentry and Li, 2014). Cai, Zhang and Henderson (2013) show that compared to English auctions, entry was deterred and prices were lower in corruption-prone two-stage auctions of the lease contracts of urban land in China. Bhattacharya, Roberts and Sweeting (2014) analyze how the pre-auction allocation of entry-rights compares to unregulated entry in the context of first-price auctions. Coviello, Guglielmo and Spagnolo (2017) show that buyer discretion in restricting entry did not lead to worsening of ex ante or ex post procurement outcomes in Italian procurement auctions of relatively complex public works in the construction sector.

In the next section, we describe the institutional environment and the public procurements. In Section 3, we outline what the available auction theory pre-

dicts we should expect to see in our data. Section 4 is devoted to describing our bid and auctions data as well as auxiliary interviews of industry practitioners. Guided by theory, we then explore the importance of endogenous bidder participation in Section 5. There we also demonstrate the role that the characteristics of the object being auctioned played. In Section 6, we analyze a number of questions related to how the procurements worked: We start by studying the price sensitivity of municipalities, followed by an analysis of who was favored and how other bidders reacted to favoritism. We then proceed to analyze how favoritism may have affected procurement costs and whether there was active or passive waste in the sense of Bandiera, Pratt and Valletti (2009). In Section 7 we discuss efficiency. We offer brief conclusions in section eight. We report a number of auxiliary analyses in an online supplement.

1 Public procurement of cleaning services in Sweden

The institutional environment

Our procurement data cover two regimes (the law changed in 2007/2008), and due to availability, come from two separate time periods: The data from the old regime runs from 1990 to 1998 and that of the new regime from 2009 to 2010. Conditional on a municipality having decided to procure, the two regimes differed in the types of auctions that the municipalities were, by law, required to organize.^{vi}

During the old regime, the law on public procurements in Sweden stated that the lowest bidder should in general, have won (see Appendix A). However, due to an exception to this rule, municipalities had the freedom to deem that some other bid than the lowest was most advantageous economically when quality, environmental aspects, service and maintenance etc. were also taken into account.

The old procurement law thus allowed the municipalities exceptionally high degrees of freedom in picking the winner *without* committing to an award rule (i.e., to organize *Beauty contests*).

During the new regime, the law was more stringent and imposed more constraints. The new law stated that the municipalities were allowed to use either the lowest-price-principle, which corresponds to a sealed bid first price auction (*First price*), or the so-called economically most advantageous tender principle, which corresponds to a sealed bid first scoring auction (*Scoring*). The law required that the call for tender explicitly specify how bids will be evaluated and ranked after the bids have been screened against mandatory qualification and exclusion criteria. This scoring rule was to be posted in advance. Explicit weighing of different criteria was the guiding principle with scoring (for a more detailed account, see Bergman and Lundberg 2013).

The two regimes differed in how entry was regulated. During both regimes, the law allowed the municipalities to decide whether to allow free entry or not (see Appendix A). Conditional on restricting entry, the law allowed the municipalities to freely decide how many and which suppliers to invite. Municipalities often regulated entry in the old regime, but very often allowed free entry in the new regime. Unlike in the old regime, the process of awarding a cleaning contract in the new regime followed a two-step procedure after the bids had been submitted: In the first step, bids were screened against mandatory qualification and exclusion criteria. The problematic bids that did not meet these criteria were disqualified. In the second step, qualified bids were evaluated according to the pre-specified award rule (i.e., *First price* or *Scoring*).

Procurement practices

In our data, a procurement event is an instance where a municipality purchases cleaning services for one or more of its buildings and premises. Such a procurement event can consist of one or more sealed-bid auctions, each allocating a single cleaning service contract to the winning bidder. One contract can cover the cleaning of more than one building. However, combinatorial bidding was not applied: During both regimes, the bidders were allowed to submit only one bid per contract and the municipalities should have made decisions contract-by-contract.

The timing of events in the procurement process was roughly as follows: First, the municipal procurement agent chose the auction format and entry mode (free or restricted entry). The municipal procurement bureaucrats also had to make decisions about the object of each separate auction, such as which buildings a single contract covered, what the cleaning frequency was, and how long the contract was. As far as we know, reserve prices were not set. The procurements were openly and centrally advertised during both regimes, although the media changed over time. After seeing the call for tenders, a two-stage auction followed: In the first stage, the (invited) suppliers made the participation decision. The firms were not informed about who were invited when entry was restricted, but this does not mean that they could not have learnt it somehow. In the second stage, the participating suppliers submitted their bids. The municipal procurement bureaucrats then chose the winner according to the award criteria to which they had committed (if any).

Like in the US timber auctions studied by Athey, Coey and Levin (2013), there are different types of bidders in our data: Large nationally active firms, regional firms, local firms operating in a single municipality, and “inhouse units” of the municipalities. It is unlikely that these bidders were symmetric. In particular,

the inhouse units differed from the other bidders. They are publicly owned organizations that share features of a public firm and that participated in the auctions as self-standing operative units. It is hard to pin down exactly what the objective function of these publicly-controlled units was; Boycko, Shleifer and Vishny (1996) have for example argued that public firms of this type may be under pressure to increase local employment. The presence of such a bidder introduces an asymmetry and an aspect of mixed oligopoly to competition (de Fraja & Delbono, 1989).

The difference in entry regulation between the two regimes affected participation through two channels: First, the introduction of the two-step procedure changed how municipalities could exclude problematic bidders. In the old regime, one instrument for that was to not have free entry and to invite only “desirable” bidders, i.e., bidders who fulfilled (unannounced) prequalification requirements. In the new regime, free entry became the norm, but the mandatory qualification and exclusion criteria were then used to disqualify problematic bidders. Second, the regime change increased bid preparation costs, as the content of the calls for tender and the preparation of a bid became more detailed and involved (red tape).^{vii} As e.g. Bandiera, Prat and Valletti (2009) have emphasized, rule-based procurement regulation and more formal procurement processes, characterized by detailed product requirements and bidder qualifications, make procurement burdensome for potential bidders and increase the entry costs. In the new regime, suppliers had to pay more attention to the mandatory qualification and exclusion criteria in order to reduce the risk that their bid would be disqualified.

As to the choice of the auction format, a look at the procurement documents of the old regime reveals that *no* municipality committed to an award rule. The procurement bureaucrats chose to use beauty contests, where the rule, if any, to

choose the winner was not disclosed to the bidders. It is illustrative of the atmosphere of the time that the freedom allowed by the law to deviate from choosing the lowest bid was seen as beneficial. The following quote from a book by a public sector lawyer testifies to this:

“The tender having the lowest price offered should be accepted. If it has been stated in the advertisement that the most economically advantageous tender will be accepted, factors specified therein can be taken into consideration in the assessment of tenders. The factors can be stated according to a degree of priority (LOU 1 ch. 22§), however this is not a requirement. On the contrary, it can be advantageous to state in the advertisement that such factors are non-prioritized, as this increases the possibility of being able to choose the contractor.” (Löfving, 1994) p.65 (our translation, and italics).

Who benefits and why is open to debate, as this kind of flexibility opens the door also for inefficient and undesirable practices. For example, Tadelis (2012, p. 301-302) argues that *“allowing for greater discretion in contractor selection increases the possibility of favoritism, kick-backs and political corruption”*.

The situation was quite different in the new regime as the municipalities had to choose either a first price auction or a scoring auction. A perusal of the procurement documents of the new regime shows that all municipalities specified a scoring rule, unless they used the lowest-price principle (first price auction). The specific design of scoring rules differ (Bergman & Lundberg, 2013), but it were described in detail either in words or in combination with a mathematical expres-

sion (see Appendix A for a summary of the mandatory qualification and exclusion criteria and scoring rules).^{viii}

The object of procurements: Cleaning service contracts

Delivery of internal regular cleaning services is a comparatively simple production process. Cleaning of floors of various types of rooms and corridors, desktop surfaces and lavatories requires relatively unskilled labor and moderate amounts of capital (e.g., cleaning equipment, washers, and vehicles) and intermediate inputs (e.g., cleaning substances and tools).

The extensive documentation available to us on the technical specifications of the procurements and the specifics of the bids suggest that there was limited room for quality differences in the cleaning services. Nor was there much scope for non-contractible quality (Spagnolo, 2012). The most compelling support for these claims is provided by the technical specifications of the procurement instructions. The procurement instructions were in general quite detailed already in the old regime. Besides including a detailed description of the premises to be cleaned, the frequency of cleaning, cleaning method, cleaning substances that are preferred and cleaning equipment that is to be employed, they also went into much more minute detail. For example, it was common to state requirements as to the professional education of cleaning staff to be used. As if this wasn't enough, in several instances the procurement instructions went into great detail as to how each space (e.g., classroom, toilet) was to be cleaned. The instructions for the preparation of a bid were quite similar in the new regime, but they were even more detailed and took the form of mandatory qualification and exclusion criteria.

The monitoring of *delivered* cleaning was often specified, too. It was standard to require the supplier to inform the municipality on several features of the

working process, to provide records of hours of work, workforce and machinery employed etc. Importantly for us, according to our auxiliary interview evidence, the industry practitioners seem to agree with the view that delivered quality did not differ between the two regimes.

2 Theoretical framework

The above description of the institutional environment and procurement practices suggests that we need a theoretical framework that encompasses i) the regime change from the beauty contests to using rule-based auction formats; ii) the changing entry costs and endogenous participation by asymmetric bidders; and iii) the governance of entry by the organizers of the procurements.^{ix}

Discretionary vs. rule-based auction formats

A shift away from using the discretionary beauty contests to only using more rule-based competitive auctions is frequently believed to improve efficiency and reduce inappropriate practices (Klemperer, 2002; Tadelis, 2012; Bajari, Houghton, and Tadelis, 2014). The first price sealed bid auction is optimal and cost-minimizing for a fixed number of bidders, when the bidders are symmetric and have independent private costs (Myerson, 1981; Riley and Samuelson, 1981). Asker and Cantillon (2008) have shown that when differentiated goods are purchased, simple linear scoring auctions dominate beauty contests and price-only auctions with minimum quality thresholds in the sense that the latter two generate lower (or equal) expected utility for the organizer of the procurement (Che, 1993; Asker and Cantillon, 2010).

Due to the simplicity of the product we study, ex ante tilting the award rule in some non-price dimension via a scoring rule is unlikely to lead to significant

welfare gains (in contrast to, e.g., the US highway procurements studied by Lewis and Bajari 2011). Moreover, unlike what has been found for some of the more complicated contracts (Bajari, Houghton, and Tadelis, 2014; Decarolis, 2014; Decarolis and Palumbo, 2015), ex post negotiations of significant adaptations to the scope of work or of cost overruns are unlikely. There also is less scope for provision of non-contractible quality (Spagnolo, 2012; Coviello, Guglielmo, and Spagnolo, 2017) and less cost uncertainty over the duration of the contract than there is, say, in completing a major construction work (Spulber, 1990). These considerations suggest that the procurement auctions of cleaning contracts are quite similar to auctions for standardized goods. Theory therefore suggests that holding other things constant, the procurement costs ought to be lower on average in the more rule-based new regime.

Favoritism and endogenous entry

Theoretical guidance gets more involved when bid preferences (favoritism) and endogenous entry are allowed. When some types of bidders are preferred either explicitly (Myerson, 1981; McAfee and McMillan, 1989; Vagstad, 1995) or implicitly, as may happen in beauty contests (Klemperer, 2002; Yoganarasimhan, 2016) the basic theoretical prediction is that favoring high-cost suppliers may reduce procurement costs due to the increased aggressiveness of the un-favored suppliers (McAfee and McMillan, 1989). This prediction however holds in special contexts only. For example, if endogenous participation is allowed (Marion, 2007; Krasnokutskaya and Seim, 2011; Athey, Levin, and Seira, 2011), there are at least three mechanisms that may increase procurement costs: Favored suppliers can increase their bids; un-favored low-cost suppliers may win less often; and the willingness of different supplier types to participate may change. The last of these

mechanisms means that when the procurement agent prefers a certain bidder type, endogenous participation can reduce overall entry and/or lead to a compositional change towards high cost bidders. The prediction for the cost effect is ambiguous, but the empirical results of Marion (2007) and Krasnokutskaya and Seim (2011) suggest that the participation margin matters a lot and that if high-cost bidders are favored, we should expect higher procurement costs in the beauty contests of the old regime.

Favoritism in public procurement may also take the form of outright corruption (Compte, Lambert-Mogiliansky, and Verdier, 2005; Menezes and Monteiro, 2006; Tran, 2008; Bandiera, Prat, and Valletti, 2009; Cai, Zhang, and Henderson, 2013). The precise mechanism of how bribes are paid and which types of favors the procurement agent provides depend on the context and how much discretion the procurement agent has when allocating the contracts. For example, Tran (2008) analyzes how the bids and bribes paid varied when the law governing the procurements changed. Using data from a bribe-paying firm, Tran compares a period when no auctions were required to periods when mandatory best-value auctions or best-price auctions were used. In Tran's data, the key mechanism through which corruption worked were secret auctions that were run before the formal auction. The tender requirements of the formal auction were then designed so that they favored the winner of the secret (bribery) auction.

The mechanical effect that results from a supplier expecting to pay a bribe is to increase its bid price, especially if the arrangement means that it can expect to win the contract at a higher price. Corruption may also lessen competition because it increases the risk of collusive coordination by bidders (Compte, Lambert-Mogiliansky, and Verdier, 2005). It may in addition lead to a choice of auction format that results in higher prices and allows corruption to continue (Cai, Zhang,

and Henderson, 2013). These considerations suggest that the procurement costs ought to be higher in the beauty contests of the old regime.

One likely consequence of more rule-based procurement processes and more detailed product requirements and bidder qualifications was that it increased entry costs of potential bidders. The theory of two-stage auctions with costly entry – see e.g. Ye (2007), Li and Zheng (2009; 2012), Marmor, Shneyerov and Xu (2013) Bhattacharya, Roberts and Sweeting (2014) – suggest that a number of (offsetting) effects may be at work. If potential bidders have no private information about their production costs as in Levin and Smith (1994), there is no compositional (selection) effect, but entry decreases when entry costs increase. In the more plausible scenario in which the potential bidders have at least some information about their costs, free entry results in the more cost-efficient suppliers entering. This means that when entry costs increase, there also is a compositional effect. Li and Zheng (2009) identify an entry and a competition effect of potential entry. They show that the positive entry effect may dominate the standard (negative) competition effect even in a standard independent private value setting. The literature on entry in auctions also suggests that regulating entry can be efficient, because the entry costs are indirectly born by the buyer (Ye, 2007) and because it can lead to a more efficient selection of bidders (if properly implemented; see Bhattacharya, Roberts and Sweeting 2014).

The above-listed theoretical insights do not provide clear-cut predictions for us: On one hand, we expect decreased *actual* entry into free entry auctions in the new regime. Holding other things constant, this ought to increase procurement costs. There may also be an offsetting effect, because the more cost-efficient suppliers became more likely to participate in the price only and scoring auctions of the new regime. On the other hand, the possibility of favoritism further compli-

cates the predictions: Less favoritism may lead to less aggressive bidding by the un-favored firms and also change the composition of participants.

3 Data

Data sources

Our bidding and procurement data come from two surveys. The first survey was administered to all Swedish municipalities asking them for procurement documents regarding internal cleaning services (Lundberg, 2005). The documents are call for tenders or contract notice, technical specification, list of bidders, bids, and the decision protocol stating the winner of the contract. The first survey is the source of the data for the first of our regimes (1990-1998).^x For the second survey the sample of procurement auctions was identified using a procurement database that keeps track of calls for tenders in Sweden. For more details see Lundberg et al. (2015).^{xi} Additional information was collected for the municipalities that according to the procurement database had organized at least one procurement auction. The second survey, carried out in 2011, is the source of the data for the new regime (2009-2010).

Our third source of data is a set of semi-structured interviews that we conducted in summer 2015. We interviewed 22 individuals who had been involved in Swedish public procurements either during the old or the new regime, or during both. The respondents were chosen for their current or former employment at one of the municipalities that our procurement auction data cover. These interviews supplement our econometric analyses.^{xii}

Descriptive statistics

Table 1 gives basic descriptive statistics, conditioning on the regime (and auction type). Our data include 1075 auctioned cleaning contracts. This total consists of 720 beauty contests that were organized in the old regime, and 240 scoring auctions and 115 first price auctions that were run during the new regime. The total number of bids in the data is 7427.

Panel A of Table 1 describes procurements, premises and contracts. In our data, the number of contracts auctioned in a procurement event decreased over time. Each contract was the object of a separate sealed bid auction, but often covered more than one premise. The premises to be cleaned are schools, offices, day care centers, other types of municipal buildings and their combinations. We take their distribution to be exogenous for our purposes. The total size of the premises that a single contract covered (measured in square meters, m²) was larger in the new regime. Municipalities also used longer contracts and extension periods in the new regime.^{xiii} The average cleaning frequency did not change much over time and was 231 ($= 5 \times 52 \times 0.89$) days per year on average. Changing the features of the cleaning contracts (e.g., their coverage in terms of size) is a decision taken by the municipalities that affects costs of organizing procurements and supplier participation. As we later argue, the Swedish municipalities may have deliberately modified the *objects* of procurement auctions – and thus an aspect of overall procurement auction design – so as to induce entry.

Panel B of Table 1 describes the mode of entry and participation. Free entry was used much more often in the scoring and first price auctions of the new regime than in the beauty contests of the old regime. Actual entry (n) refers to the number of bids submitted in an auction. The raw data reported in Table 1 appears

to suggest that there was less actual entry in the new regime (this difference disappears when observables are controlled for). In the new regime, a small number of bids were disqualified. Potential entry (N) refers to the total number of suppliers that submitted at least one bid in a given municipality in our data during the old and new regimes (for a similar approach, see, e.g. Li and Zhang, 2010; Athey, Levin and Seira, 2011; Li and Zheng, 2012; Athey, Coey and Levin, 2013). To allow for the possibility that potential entry to the largest auctions was different (e.g., due to the smallest local firms not participating in them), we calculate potential entry separately for large and small contracts in each municipality, with the threshold for a large contract set at the 80th percentile of the distribution of the (total) size of the premises included in the contract.^{xiv} On average, the number of potential bidders was about 19.

[TABLE 1 HERE]

There are four main types of bidders: Large nationally active firms (“national”), inhouse units of the municipalities that participated in the auctions as self-standing operative units (“inhouse”), small local firms (“local”), which we define as those firms that are not national or inhouse units and that participated in auctions of only one municipality, and regional firms (“regional”), which we define as those firms that are not national or inhouse units and that participated in auctions of more than one municipality.

As Table 1 shows, the rate of participation by inhouse units (and, to some extent, local firms) was lower in the new than in the old regime. Conditional on participation, the probability of an inhouse unit winning decreased moving from the old to the new regime. Conversely, the probability of national and regional firms winning increased in the new regime.

Panel C of Table 1 describes the bids. To achieve comparability across auctions, the bid is measured using the deflated price of the cleaning service per square meter and day (frequency).^{xv} In our analysis, we also control for the type of the premises and other characteristics of the contracts and allow for scale economies. As Panel C of Table 1 shows, the average and median bids, calculated over all submitted bids (and not just winning bids), are somewhat lower in the beauty contests than in the scoring and first price auctions of the new regime. The same applies to the minimum bids. However, the average winning bids are almost the same in the two regimes and in the three auction formats. This finding means that, unconditionally, the procurement costs were not lower in the new regime. This is a striking observation, because we can also see from Table 1 that the lowest bidder won only 42% of the time in the beauty contests. Moreover, conditional on not choosing the lowest bidder, the municipalities ended up paying on average 43% more than the lowest bid in those auctions. In the new regime, the lowest bidder won much more often: When calculated over both the scoring and first price auctions, it won 76% of the auctions.

Descriptive regressions

The raw data showed that the procurement costs were not lower in the new regime. We have run a set of exploratory reduced-form regressions to check whether that also holds when we condition on observable auction and municipality characteristics. In these regressions, the dependent variable is the logarithm of the winning bid. The regressions confirm that the winning bids were not lower in the new regime (see Appendix B).

The law change in Sweden was a product of EU wide developments, which resulted in stricter procurement regulation and induced a quasi-exogenous switch

away from using the beauty contests. The obvious question is: Why didn't the shift from the discretionary beauty contests to rule-based auctions reduce procurement costs?

4 Winning bids and entry

Our review of the available theory and prior empirical work suggested that possible determinants of the competitiveness of the procurement outcomes are endogenous bidder participation (number of bidders) and changing scope for not choosing the lowest bidder (favoritism). We explore the former in this section, and the latter in the next section.

The econometric approach

To explore how the regime change and bidder participation are related to procurement costs, we model the conditional mean of the winning bids (per unit of square meter and day) using the following specification:

$$E(Bid|R, W, X, T, \mu, n) = \exp[\beta R + \alpha \ln(n) + W'\lambda + X'\theta + \gamma T + \mu] \quad (1)$$

where R is a dummy equal to one if the auction was organized in the new regime and zero if it was organized in the old regime and n measures actual entry. The parameter α measures the entry elasticity of procurement costs and tells us how important entry is for the competitiveness of the procurement.

Because the raw data suggest that object characteristics changed over time, we use two groups of explanatory variables. The first group, denoted W , includes the number of contracts (*Auctions per procurement*) awarded in the procurement event, the size (in 10 000 square meters) of the premises covered by the contract (*Size of premises*) and its square, the length (in years) of the contract (*Contract*

length), the number of years over which the contract can optionally be extended if the municipality so decides when the initial contracting period expires (*Extension*), and the scaled number of days during which the cleaning takes place (*Frequency*) and its square.^{xvi} The second group, denoted X , consists of dummies for types of premises covered by a contract (*School*, *Office*, *Day-care center*, *Other*), municipal unemployment rate (*Unemployment*), population density (*Population density*) in thousands of inhabitants per square kilometer, share of inhabitants having a higher education (*Education*) and a binary indicator for those municipalities where leftwing parties have more than 50 percent of the seats in the municipal council (*Red majority*).^{xvii} We take X as exogenous, but consider the possibility that W is potentially determined by the municipalities (so as to govern entry).

We also include a vector of municipal fixed effects, μ ; one of the fixed effects refers to the group all those municipalities that organize less than five auctions. We include a linear within-sample trend, T , because the regime change may have coincided with an underlying unobserved trend in cleaning costs (due to e.g. technological development).^{xviii} We control for this possibility also using the other time-varying (municipal) covariates.

Identification of the effect (α) of actual entry on the winning bid in (1) may be hampered by the endogeneity of n . For example, suppliers may be more willing to pay the entry cost and enter a procurement auction if they expect the winning bid to be higher. Consequently, we model actual entry using the following conditional mean specification as our first stage:

$$E(n|R, W, X, T, \mu, F) = \exp\left[\tilde{\beta}R + W' \tilde{\lambda} + X' \tilde{\theta} + \tilde{\gamma}T + \tilde{\mu} + F' \tilde{\kappa}\right] \quad (2)$$

where $F = \{Free\ entry, Free\ entry \times R, Ln(N)\}$ is the vector of instruments and $\tilde{\kappa}$ is the associated vector of parameters.

The identifying assumption in using *Free entry* as an instrument is that restricting entry into an auction affects winning bids only through its effect on actual participation. It is our understanding that in the old regime, municipalities restricted entry partly in order to exclude problematic bidders. Our interpretation of the industry practice is that restricted entry was a means to reduce hassle costs of dealing with unreliable bidders. In contrast, the two step procedure described earlier was applied in the new regime to screen the submitted bids against the mandatory qualification criteria. This means that in the new regime, not allowing for free entry likely played a much smaller role in deterring participation by problematic bidders.^{xix} Our exclusion restriction would be violated if *Free entry* affected not only the amount of entry, but also its composition. One of our robustness tests is therefore to control for the types of bidders.

We allow for regime-specific differential effects by using the *Free entry* - indicator and its interaction with the regime -indicator (*Free entry* \times *R*) as instruments. If entry restrictions were used to deal with the hassle costs caused by problematic bidders especially in the old regime, we expect *Free entry* to get a positive coefficient.^{xx} The coefficient of *Free entry* \times *R* should imply a smaller effect of free entry on actual entry in the new regime.

We use potential entry ($\ln(N)$) as an additional instrument for actual entry $\ln(n)$. Here, the exclusion restriction is that the number of potential bidders has no effect on the winning bid beyond its effect on the number of actual bidders. Also this assumption could be violated through a composition effect that we address in our robustness tests. The benefit of using potential entry as an instrument is that it allows us to also explore whether the effect of entry on winning bids depends on the type of the entering bidder(s).^{xxi}

Our instruments $F = \{Free\ entry, Free\ entry \times R, Ln(N)\}$ predict actual entry well and our main IV results are also robust to using estimation techniques which allow for weak instruments. Moreover, we use the method of Conley et al. (2012) to explore how strongly our results depend on the identification assumption that the decision to restrict participation was not systematically related to the expected competitiveness of an auction. The method allows us to show how, if at all, our baseline results change if we allow $\{Free\ entry, Free\ entry \times R\}$ to be mildly positively correlated with the unobserved component of the winning bids in the second stage, violating our exclusion restriction. This case would correspond to a situation in which municipalities were more likely to allow free entry into auctions in which the expected winning bid was higher.

Our focus on the regime change means that we compare the beauty contests with what happened on average in the new regime's first price and scoring auctions. That is, we group the scoring auctions together with the first price auctions and contrast how the new, more rule-based regime differs from the old discretionary regime. When estimating (1) and (2), we nevertheless at times allow separate effects for the first price and scoring auctions of the new regime.^{xxii} We do so to illustrate the robustness of our findings, *not* to estimate the (causal) effect on procurement costs of using a first price auction instead of a scoring auction.^{xxiii}

Instrumental variable estimations

First-stage results for actual entry

We report the first-stage regressions for actual entry in Table 2. The dependent variable is the logarithm of the number of submitted bids ($Ln(n)$).^{xxiv} Besides the regime dummy (or its variants; see below), the vector of explanatory variables includes W , X , T and the municipal fixed effects.

We report results from three different specifications. Model 1 is our preferred first stage specification: In this model, we include R and the vector of instruments, is $F = \{Free\ Entry, Free\ Entry \times R, Ln(N)\}$. In Model 2, we keep the instrument vector unchanged but substitute *Scoring* and *First price* -indicators for R . In Model 3, we allow for a slightly extended instrument set of by substituting $Free\ entry \times Scoring$ and $Free\ entry \times First\ price$ for $Free\ entry \times R$. We acknowledge that the choice by a municipality to use *Scoring* or *First price* auction may be endogenous: We report the results for Models 2 and 3 only to show that our findings are *not* due to the way we treat the regime / auction format dummies.

[TABLE 2 HERE]

Table 2 shows that the coefficient of *Free entry* is positive and highly significant in our preferred Model 1: The use of restricted entry was associated with fewer actual entrants in the beauty contests. However, the coefficient of the interaction term between the free entry and regime indicator is negative and significant and almost of equal absolute size with the coefficient of the *Free entry* -indicator. In the new regime, allowing *Free entry* became the norm (recall Table 1) and, as the sum of the coefficients show, it had no effect on actual entry. This finding is consistent with the view that there was less need in the new regime to screen problematic bidders out by restricting entry.^{xxv} Table 2 also shows that the elasticity of actual entry w.r.t. potential entry is always highly significant (and close in size to the elasticity estimate of 0.4 reported in Li and Zheng 2009). The F-test reported for Model 1 in the table suggests that the instruments are not weak. The results for Models 2 and 3 confirm the findings made from Model 1.

Figure 1 illustrates the economic meaning of the first stage estimates. Panel A reports the sample means of the logarithm of actual entry, $Ln(n)$, for the old and

new regime. The raw data suggest that there was less actual entry in the new regime. The mechanisms at work are however more complicated, as shown in Panels B, C and D.

In Panel B we ask how changes in the instruments, F , and regime, R , affect predicted entry. The difference in the height of the bars in Panel B shows that, keeping other things constant, the predicted entry decreases by 23% when R and F change from their values in the old regime (left bar) to the values they obtain in the new regime (right bar).^{xxvi} Going beyond what is shown in Panel B, consider a free entry auction, holding all other things constant: If we now change the regime indicator from zero to one, the predicted actual entry decreases by 42% (p-value < 0.01). This says that there was much less entry into a free entry auction of the new regime than into a similar free entry auction of the old regime. These findings suggest that had other things remained constant, entry would have reduced after the regime change.

In Panel C, we explore how changes in contract characteristics, W , affect entry, holding other things constant. The left bar displays predicted entry when W is set to the means of the old regime and the right bar displays predicted entry when W is set to the means of the new regime. The heights of the bars differ, because the municipalities increased in the new regime the length and extension periods of the contracts and the total size of the premises that each contract covered (see Table 1). The first stage estimates imply that such changes are associated with more entry. These contract changes *increased* entry by 19.5% moving from the old to the new regime. The difference in the heights of the bars is statistically significant (p-value < 0.01).

Panel D of Figure 1 displays the *combined* effect of regime changes (shown in Panel B) and contract changes (shown in Panel C) on entry: As the panel shows, the net effect of all of these changes on entry is very close to zero.

[FIGURE 1 HERE]

To sum up, we find that, overall, entry *did not* change from the old to the new regime. This net effect masks however many mechanisms at work. Holding other things constant, predicted entry was lower in a free entry auction of the new regime, when compared to a similar free entry auction of the old regime. A likely reason for the lower entry in the free entry auctions of the new regime is that red tape and thus participation costs increased in the more rule-based procurement environment; increased red tape also came up in our interviews of the industry practitioners. Another possible reason for it is that potential entrants anticipated the increased emphasis on price (see the next section) and thus a more competitive auction. Indeed, entry would have decreased, had the municipalities not adjusted the objects of the auctions by making the contracts “larger” e.g. by increasing the total size of the premises that each contract covered as well as the length and extension periods. This interpretation of the first stage estimates is consistent with our informal discussions with practitioners, who mentioned that longer extension periods and larger auctions are a means to influence the amount of entry.

Second stage results for winning bids

We report in Table 3 an OLS regression and a set of IV (2SLS) regressions in which the dependent variable is the logarithm of the winning bid. The first column reports the OLS estimates and the remaining columns refer to the IV estimates: Models 1 to 3 correspond to the second stage of the first stage regressions reported in Table 2, with Model 1 that uses the regime dummy being our preferred spec-

ification. . Again, we report the results for Models 2 and 3 only to show that our findings are *not* due to the way we treat the regime/auction format dummies.

The first column shows that the OLS estimate of the entry elasticity of the winning bid is -0.11 and significant, suggesting that more entry is associated with lower procurement costs. However, our preferred IV model (Model 1) produces a much larger and highly significant elasticity estimate of -0.55. The upward OLS bias is intuitive, indicating that there was more entry into auctions where the (potential) bidders expected the winning bid to be high. The last two columns of the table show that the result for the entry elasticity does not depend on how we treat the regime indicator (or the auction type indicators) in the model.^{xxvii} The estimated entry elasticity of the winning bid shows that securing entry is very important for competitive procurement outcomes in our data.

[TABLE 3 HERE]

Figure 2 consists of four panels, each illustrating the economic implications of the second stage estimates of our preferred model (Model 1 of Table 3). Panel A reports the sample means of the logarithm of the winning bids, $\ln(\text{winning bid})$, for the old and new regimes. This panel confirms that the unconditional procurement costs were very similar in the two regimes. Panels B, C and D present decomposition similar to the one we used in Figure 1 and illustrate the complexity of the mechanism at work. Panel B shows that, keeping other things except the regime constant, the predicted bids were slightly lower in the new regime.^{xxviii} Panel C displays how contract changes (changes in W) directly affect the winning bids, going from the old to new regime: They resulted in slightly higher winning bids in the new regime.^{xxix} Finally, Panel D shows the total effect of these changes (shown in Panel B and in Panel C) on the winning bids. For Panel D we additionally allow entry to adjust and to take its regime-specific predicted values, as im-

plied by the first-stage estimates. The net effect of all the changes on the winning bid is very small: The two bars are almost of equal height.

To sum up Figure 2, we conclude that for a typical municipality and premise (e.g. school) that was to be cleaned, procurement costs *did not* change from the old to new regime. Our IV findings and decompositions are hence consistent with what the raw data and reduced form regressions already suggested. However, as Figures 1 and 2 show, a number of counter-balancing adjustments took place simultaneously.

[FIGURE 2 HERE]

The decompositions presented in Figure 1 and 2 showed that the procurement costs would *not* have been the same in the two regimes if the municipalities had not induced more entry in the new regime by adjusting the objects of auctions. To see how important securing entry was, we can check what the effect of the documented 23% reduction in entry (see Panel B of Figure 1) would have been on the winning bids had the municipalities not neutralized it. The second stage estimates imply that holding other things constant, the effect of such a decrease in entry would be to increase bids by 12.5% (p-value < 0.01).^{xxx}

Robustness

We have considered the robustness of our baseline IV results in a number of ways (see Appendix C): i) We checked that the estimated entry effect is not due to a compositional effect, i.e., due to different types of suppliers winning in auctions with more entry; ii) we considered in a number of ways the possibility that our instruments are weak; iii) we evaluated the plausibility of our exclusion restrictions using the approach developed by Conley, Hansen and Rossi (2012); iv) we re-ran our analyses using an alternative measure of potential entry and an al-

ternative estimation sample; and v) we checked that outlier bids are not driving our findings.

5 Favoritism

If reduced entry does not explain why the winning bids were not lower in the more rule-based new regime, then what does? In this section we turn to the other possible determinant of the competitiveness of the procurement outcomes, i.e., the change in the scope for not choosing the lowest bidder.

Price sensitivity of municipalities

We first show that *decreased* price sensitivity of municipalities cannot explain why there is no difference in the average winning bids of the two regimes. The reason we pay attention to price sensitivity is that in our data, roughly two thirds of the auctions in the new regime were scoring auctions (see Table 1). The scoring rules could have made the municipalities less price sensitive in the new regime than in the old. If they did, it would explain why the winning bids did not change when the regime changed.

To obtain a benchmark, we use auxiliary data on the scoring rules used in the new regime (see Appendix D) to calculate the average weight attached to the bids in the auctions of the new regime. The average weight was about 0.7. To estimate the change in price sensitivity, we study the procurement bureaucrats' choice of the winning bid using a random utility model (McFadden, 1974), i.e., the Conditional logit model.^{xxxi} The model is estimated using submitted bids and not just the winning bids. The more negative the coefficient of the bid is in these estimations, the more weight the price received in the choice of the winner.

Table 4 reports the estimation results for six different Conditional logit models (Models 1 to 6). In the first four models, data for *First price* auctions are excluded from the estimations, because in them the bids completely determine the choice of the winner. Models 1 to 4 therefore focus on the difference in price sensitivity between *Beauty contests* and *Scoring* auctions. The key explanatory variables are *Bid* (in krona per square meter and per day), which captures the price sensitivity in the *Beauty contests* of the old regime, and its interaction with the scoring indicator, $Bid \times Scoring$. The coefficient of the interaction term tells us how the price sensitivity differs in the scoring auctions relative to the beauty contests. In Model 1, there are no additional explanatory variables. In Model 2, we include the number of bids that each supplier submitted in the particular procurement and the total number of bids that each supplier submitted during the entire observation period. We use the former variable to control for the possibility that the municipalities take in the account how active the suppliers are in the particular procurement event (i.e., the potential multi-unit nature of the procurement). We use the latter variable as a crude proxy for the reputation of the suppliers in the market. In Model 3, we replicate the estimations of Model 1, except that we now add the supplier type dummies (*Local*, *Regional*, *National*; omitted: *In-house*) and their interactions with the indicator for the scoring auctions. Model 4 replicates Model 3, except that we now also add the two firm-level controls from Model 2. Finally, Models 5 and 6 are equivalent to Models 3 and 4, respectively, except for two things: First, they are estimated using a sample which also includes *First price* auctions and second, in these models $Bid \times R$ has been substituted for $Bid \times Scoring$. The new interaction tells us how much more (or less) price sensitive the auctions were in the new regime on average.

[TABLE 4 HERE]

Models 1 to 4 reported in Table 4 yield two main findings. First, the coefficient of *Bid* is negative and highly significant, implying that a higher bid reduced the probability of winning in the old regime. Second, the coefficient of the interaction term, *Bid* \times *Scoring*, is negative and highly significant. This finding means that the procurement bureaucrats were less price sensitive in the beauty contests than in the scoring auctions.^{xxxii} The results from Models 5 and 6 provide further support for the lower price sensitivity of the municipals in the old regime. In particular, the coefficients of *Bid* and *Bid* \times *R* in Models 5 and 6 show that the weight attached to price in the beauty contents of the old regime was about a quarter ($0.26 \approx -4/(-4-11.3)$) of the weight that was attached to the bid in the new regime.

These results have two implications: First, given that the average weight attached to the price in the new regime was 0.7 (see above), the weight implicitly attached to the price in the beauty contests of the old regime was about 0.18 ($= 0.26 \times 0.7$). Second, *decreased* price sensitivity of municipalities clearly cannot explain why there is no difference in the average winning bids of the two regimes.

Our interview respondents provided additional perspective on these findings. First, a clear majority of the respondents indicated that besides inexperience in using formal scoring rules during the old regime, major reasons for not using them were convenience (86% of respondents; see Appendix D) and the freedom to pick the desired winner (77% of the respondents). Second, the respondents gave a number of reasons for not choosing the lowest bid in the old regime. Besides seeing it as a means to secure quality, the most often mentioned reason (91% of the respondents) was the need to be able to choose a particular preferred bidder, at least once in a while. Corroborating this, 80% of the respondents agreed with the view that certain types of suppliers were treated favorably in the old regime.

Who was favored? The special role of inhouse units

A useful by-product of the estimation results of Table 4 is that they allow us to take a closer look at *which* suppliers were treated favorably. As we show next, the estimations allow us to establish that, conditional on the submitted bid, it was the inhouse units that were more likely than the other types of suppliers to win in the beauty contests.

We start by zooming at Models 3 to 6 of Table 4, which include firm type dummies and in which *inhouse* units are the base category. In these models, the other suppliers' type dummies obtain statistically significant *negative* coefficients. This finding shows that the *inhouse* units were more likely than the other types of suppliers to win in the beauty contests of the old regime *conditional on the submitted bids*. This finding is in line with the raw data (Table 1), which already suggested that *inhouse* units were particularly likely to participate *and win* auctions in the old regime: They submitted a bid to 60% of the auctions of the old regime, and won half of them. Table 4 shows moreover that this pattern disappeared in the new regime: When the firm type dummies are interacted with the indicator for the scoring auctions (Models 3 and 4) or the regime indicator (Models 5 and 6), the interactions obtain positive coefficients that essentially counterbalance the direct negative effects.

The economic magnitudes are not negligible: Our estimates imply that in the beauty contests, the willingness of municipalities to pay for the cleaning services of the *inhouse* units appears to have been roughly 0.4-0.5 krona (per square meter and per day) higher than for the services of the other types of suppliers.^{xxxiii} This is a substantive amount when compared to the mean of the winning bids (0.64 krona; see Table 1). This finding motivates us to take a closer look at the special role of *inhouse* units.

The interviews provide additional support for these findings (see Appendix D). The responses of the interviewed industry practitioners suggest that although the favored supplier likely varied across municipalities, both local firms and in-house units were treated favorably. The respondents also believed that inhouse units were very rarely treated unfavorably, whereas other firms were. When specifically asked, 71% of the respondents agreed with the view that inhouse units got a favorable treatment in the old regime.

How did un-favored suppliers react to favoritism?

Theory and prior empirical work suggest that the presence of a favored bidder may affect the procurement costs and lead to more aggressive bidding by un-favored bidders firms (McAfee and McMillan, 1989; Athey, Coey, and Levin, 2013). Such behavior might explain why the more competitive rule-based auctions did not result in lower procurement costs. To explore how the *presence* of an inhouse unit in an auction affected bidding, we proceed in two steps. In the first step, we study the winning bids, using a modified version of equation (1). We then explore in the second step the bid *distribution* more thoroughly, using all submitted bids (and not just winning bids).

We start by estimating the following version of equation (1) by GMM:

$$E(Bid|\bullet) = \exp[\beta R + W'\lambda + X'\theta + \gamma T + \mu + \alpha \text{Ln}(\chi D + n - D)] \quad (3)$$

where D is an indicator variable which takes value of one if an inhouse unit *participated* in an auction, and is zero otherwise. In this model, parameter χ explicitly measures whether entry into an auction by an inhouse-unit has a *differential impact* from the entry of other types of suppliers. If $\chi = 1$, there is no difference in the entry effects; if so, we are back to our baseline model (1). Because α is likely negative, a positive χ below unity implies that the impact of entry on the winning

bid is smaller when an inhouse unit participated in the auctions. Finally, if χ is positive and larger than one, the impact of entry on the winning bid is greater when an inhouse unit participated.

We treat D as endogenous and instrument it with a measure S of an inhouse unit's relative importance among all potential bidders. If an inhouse unit ever submitted a bid in a municipality (in our data), S is one divided by the number of potential entrants, calculated separately for the large and small auctions of each municipality. Otherwise, S obtains a value of zero.^{xxxiv} The exclusion restriction is that the composition of the potential bidder pool affects the winning bid through the composition of the actual bidders only. The other instruments are as they were in our preferred IV estimation of Model 1, Table 3.^{xxxv}

Table 5 displays the results of estimating (3) by GMM. We estimate the model in log-log transformed form so that the dependent variable is the logarithm of the winning bid. The reported model specifications correspond to those used earlier in Table 4. The estimates of the first column of the table show two things. First, the elasticity of the winning bid with respect to the number of bidders is about -0.4; this compares to the -0.5 we obtained in our main specification. Second, the estimate of χ is negative, and the null hypothesis $\chi = 1$ is clearly rejected. This implies that entry by an inhouse unit *reduced* the negative impact of entry on the winning bid; it is as if there were *fewer* bidders than there actually were. The estimates from the other two models confirm these findings.

[TABLE 5 HERE]

The analysis reported in Table 5 does *not* allow us to explore the hypothesis that favoritism leads to more aggressive bidding by other firms (McAfee and McMillan, 1989; Athey, Coey, and Levin, 2013). The reason is that the winning bids are a function of both suppliers' bidding behavior and the municipalities'

choice behavior. A sole focus on the winning bids may therefore mask important features of our data. To uncover them, we proceed to take a look at the *distribution of all submitted* bids. We do so to explore how submitted bids at different points of the distribution are affected by the presence of an inhouse unit. The question we are interested in is whether the submitted bids are adjusted differentially at the different points of the distribution in response to inhouse participation. Aggressive bidding might be especially prominent in the lower tail of the bid distribution, which motivates a quantile regression analysis.

Table 6 displays the results of a reduced form quantile regression (Koenker and Bassett Jr, 1978), estimated using the sample that includes all submitted bids. The dependent variable is the logarithm of the submitted bids (inflation-adjusted price of the cleaning service per square meter and day). To focus on the more relevant left tail of the bid distribution, we report the estimates for the 5th, 10th, 15th, 25th, 50th and 75th percentiles. We use the same set of control variables (W , X , T) as before (see Appendix D for alternative quantile regression specifications). In addition, we include the indicator variable D , which takes value of one if an inhouse unit participated in an auction, as well as its interaction with the regime indicator. The coefficient of D measures how the submitted bids differed in the presence of an inhouse unit in the beauty contests of the old regime from the beauty contests in which such a unit did not participate. The reported standard errors are obtained via bootstrapping (100 replications).

[TABLE 6 HERE]

The key finding is that the indicator D obtains a negative and significant coefficient at each percentile that we report, with very little variation in the absolute value across quantiles. This means that the presence of an inhouse unit in the beauty contests was associated with *lower* bids throughout the bid distribution.

Although we cannot conclusively rule out selection, it seems implausible that the inhouse units would have intentionally participated only in the most competitive auctions of the old regime. The findings reported in Table 6 are therefore consistent with – if not suggestive of – favoritism leading to more aggressive bidding by other firms (McAfee and McMillan, 1989; Athey, Coey, and Levin, 2013). The more aggressive bidding counterbalanced the lower price sensitivity of the municipalities in the beauty contests. This counterbalancing provides a further reason for the procurement costs being similar in the two regimes.

How did favoritism affect procurement costs?

We now take a more detailed look at what the counterbalancing meant for the procurement costs. We illustrate the relative importance of supply (bidding) and demand (winner choice) behavior for the procurement costs by exploiting within-auction rankings of the submitted bids. This analysis allows us to demonstrate how the distribution of submitted bids changed and how this change was associated with the increased price sensitivity of the municipalities.

To start with, we rank the bids of each auction in our data based on their monetary component (price). We then calculate the probability of the municipalities choosing a bid of a given rank, as well as the average bid and the average winning bid for each rank.

Figure 3 reports the probability of a bid being the winning bid for the six lowest bid ranks, separately for the old (left) and new (right) regime. The figure shows that conditional on a bid being in ranked the lowest or the second lowest, the probability of it being the winning bid is much higher in the new regime than in the old regime. Reflecting this difference, about 60% of the winning bids of the old regime and about 90% of the winning bids of the new regime were the lowest

or the second lowest bid of the auction. The difference illustrates how the greater price sensitivity of the municipalities in the new regime affected the distribution of *winning* bids over the ranks.

[FIGURE 3 HERE]

Figure 4 consists of Panels A to D, which display the average of the logarithm of all submitted bids and the average of the logarithm of winning bids for each bid rank, separately for the new and old regime. A comparison of Panel A to B and of Panel C to D shows that, in all the lowest ranks, the averages of the submitted and winning bids were quite a bit lower in the old regime. For example, the submitted bids in the lowest rank were on average 27% lower in the old regime than in the new regime (p-value = 0.036). Although some of the lowest bids of the old regime may not have been credible and may have been submitted by firms with poor reputation, these numbers illustrate how the left tail of the bid rank distribution changed, as predicted by McAfee and McMillan (1989).

[FIGURE 4 HERE]

Although acknowledging that it is difficult to distinguish between supply and demand side behavior without using a structural model, we use the ranks to answer a simple counterfactual question: What would the average of the logarithm of the winning bid have been in the new regime, had the average submitted bid of each rank remained as they were in the *old* regime and if the municipalities had drawn the winning bids in the same proportion from the ranks as they actually did in the *new* regime? The average of the logarithm of the winning bid would in this case have been -0.67. This compares to -0.51, which is the mean of the logarithm of the winning bid in the new regime. The difference between the two is -0.16 (p-value < 0.01). This decomposition shows that had the distribution of the submitted

bids not changed, the shift from the favoritism-prone beauty contests to rule-based auctions would have reduced procurement costs.

The ranks also highlight how the composition of the lowest ranked bidders and winners changed. In the old regime, the inhouse units submitted roughly a third of the bids in each of the five lowest ranks. In the new regime almost all of the bids in the five lowest ranks were submitted by suppliers other than the inhouse units. What's more interesting is that conditional on an inhouse unit submitting the lowest, second lowest or third lowest bid in the old regime, 78%, 49% and 45% of its bids won the auction, respectively. The corresponding percentages for the other suppliers were much lower at 35%, 15%, and 11%, respectively. The roles were almost completely reversed in the new regime.

Was favoritism active or passive waste?

Even though favoritism may have been associated with more aggressive bidding (as also the prior work suggests), it apparently did not lead to lower procurement costs. Why, then, were the municipalities so price insensitive in the old regime?

We can address this question by making use of the approach of Bandiera, Prat and Valletti (2009). Their approach allows us to explore whether or not choosing the lowest bid in the old regime is indicative of “active waste”, which means that the procurement agent directly benefited from the inflated bids. Alternatively, not choosing the lowest bid may mirror “passive waste”, which refers to X-inefficiency. Passive waste takes place when for instance poor practices and decisions lead to unintentional, inefficient spending of public resources. Application of the approach of Bandiera, Prat and Valletti (2009) to our data show (see Appendix D for details) that those municipalities that were *less* likely to choose the lowest bid in the old regime were also *more* likely to choose a scoring auction

in the new regime. This revealed preference is consistent with municipalities “actively wasting” public resources in the old regime.

What could active waste mean in the context of municipal public procurements in Sweden? In particular, was the practice of not choosing the lowest bid associated with outright corruption (Tran 2008; Cai, Zhang and Henderson 2013), or did such behavior generate some other kinds of benefits? We think that in our context, active waste is *unlikely* to mean outright corruption for three reasons: First, Sweden is one of the least corrupted countries in the world, so the institutional environment is quite different from, e.g., that of Cai, Zhang and Henderson (2013). Our understanding of the Swedish procurement practices and our discussions with the industry practitioners do not lend support for outright corruption either. Second, active waste may mirror municipalities’ intentional behavior to support employment in the favored inhouse units (McAfee and McMillan 1989; Vagstad 1995), as such public firms are arguably under pressure to increase local employment (Boycko, Shleifer, & Vishny, 1996). Some of our econometric findings are consistent with this view (again, see Appendix D for details).

Finally, the interviewed respondents provide four main reasons for the favorable treatment of the inhouse units in the old regime: Local employment, political involvement, labor union involvement, and ease of doing business with them (see Appendix D). Other reasons may also have mattered, but these reasons were mentioned by more than four out five respondents.

In sum, albeit the documented favoritism was associated with more aggressive bidding by other firms, it also seems to mirror municipalities’ intentional behavior to support the viability and employment of the inhouse units.

6 Efficiency

We have established four key findings so far: *First*, the lowest bid rarely won in the beauty contests, leaving a relatively large amount of money on the table (section 4.2). The procurement costs were nevertheless about the same in the two regimes (Section 4 and 5). *Second*, neither entry nor the procurement costs would have been the same in the two regimes if the municipalities had not induced more entry in the new regime by auctioning larger units and offering longer contracts (Section 5). Securing entry in this fashion was very important for improving the competitiveness of the auctions in the new regime. *Third*, the weight attached to price in the beauty contests was about a quarter of the weight that was on average attached to the bids in the new regime (Section 6). This was related to favoritism, as the inhouse units were often able to win the beauty contests even when they submitted higher bids than other suppliers (Section 6). Favoritism led to more aggressive bidding by other suppliers, shifting the distribution of submitted bids (Section 6). The effect of the more aggressive bidding was counterbalanced by the lower price sensitivity of the municipalities in the old regime. Had the bid distribution not changed, the shift from the favoritism-prone beauty contests to rule-based auctions would have reduced procurement costs (Section 6). *Fourth*, the documented favoritism likely mirrors municipalities' intentional behavior to support the viability and employment of the inhouse units (Section 6).

What do these findings imply for efficiency? This is a hard question to answer conclusively, but on balance, we are inclined to argue that efficiency improved in the new regime.

Quality of service and ex post renegotiations: We do not have hard data to compare the two regimes in these dimensions, but the nature of the product we

study suggests that there was relatively little scope for either the quality or ex post negotiations of adaptations to change from the old to new regime.

Our interview respondents reported experiencing some problems with quality in both regimes (e.g., some sort of inadequate delivery or non-performance; see Appendix E) but we have no evidence of quality differences across regimes.^{xxxvi} Thus increased quality is unlikely to explain why the more rule-based auctions did not decrease prices. In addition, problems in *delivered* quality or ex post adjustments rarely lead to renegotiations (see Appendix E).^{xxxvii} This is in contrast to what the prior work focusing on more complex products and contracts suggest (Bajari, Houghton, & Tadelis, 2014; Decarolis, 2014; Decarolis and Palumbo, 2015).

Cost of production: We argue that the new regime increased allocative efficiency through at least the following mechanisms: First, the price sensitivity of the municipalities increased and the supplier-level (fixed) entry costs likely increased (red tape); both of these lead to inefficient suppliers more often not participating in the new regime. Our interview evidence supports this view: Our respondents clearly indicate that the inhouse units had a cost disadvantage (Appendix E) and they participated and won much less often in the new regime. Second, our econometric and interview evidence shows that favoritism was reduced in the new regime. This change likely increased allocative efficiency. Third, it seems plausible that the transparency of the procurement and award mechanisms increased from the old to new regime. In the new regime less efficient suppliers had a more accurate estimate of their chance of winning, allowing them to opt out if the prospect of winning was poor.

In sum, we do not find systematic evidence on reduced quality, but find arguments for reduced costs. We are therefore inclined to say that allocative efficiency improved.

7 Conclusions

Conventional wisdom suggests that, absent complications, the shift to the more rule-based procurement environment of the new regime should have decreased procurement costs. It did not in the case of Swedish procurement of cleaning services. Instead, the picture that emerged from our analysis showed a complex reality, involving favoritism that targeted high cost suppliers in the old regime as well as increased red tape and redesign of auction objects in the new regime. Our findings augment the prior literature on how different auction formats and particularly bid preference programs work (McAfee and McMillan, 1989; Marion, 2007; Krasnokutskaya and Seim, 2011; Athey et al., 2013), because the beauty contests that we have studied were not based on an explicit price-preference rule.

A more rule-based procurement environment indeed curbs favoritism. The expected cost savings of reduced favoritism do not necessarily come about unless one pays attention to the importance of endogenous entry for procurement costs and, simultaneously, to changes in the bidding behavior of suppliers.

In Sweden, allocative efficiency seems to have improved going from the old, favoritism-prone regime to the more rule-based new regime. However, the numerous changes and mechanisms at work prevent us from pinning down how welfare changed: A central complicating factor is how to evaluate welfare implications of aggregate entry costs over bidders and auctions in the two regimes, as well as the lost (local) welfare due to the municipalities not being able to support

local employment, especially in the public sector, by awarding contracts to in-house units in the new regime.

Control variables (W, X, T)	Yes	Yes	Yes	Yes	Yes
Municipal FE	Yes	Yes	Yes	Yes	Yes
Observations	7,364	7,364	7,364	7,364	7,364

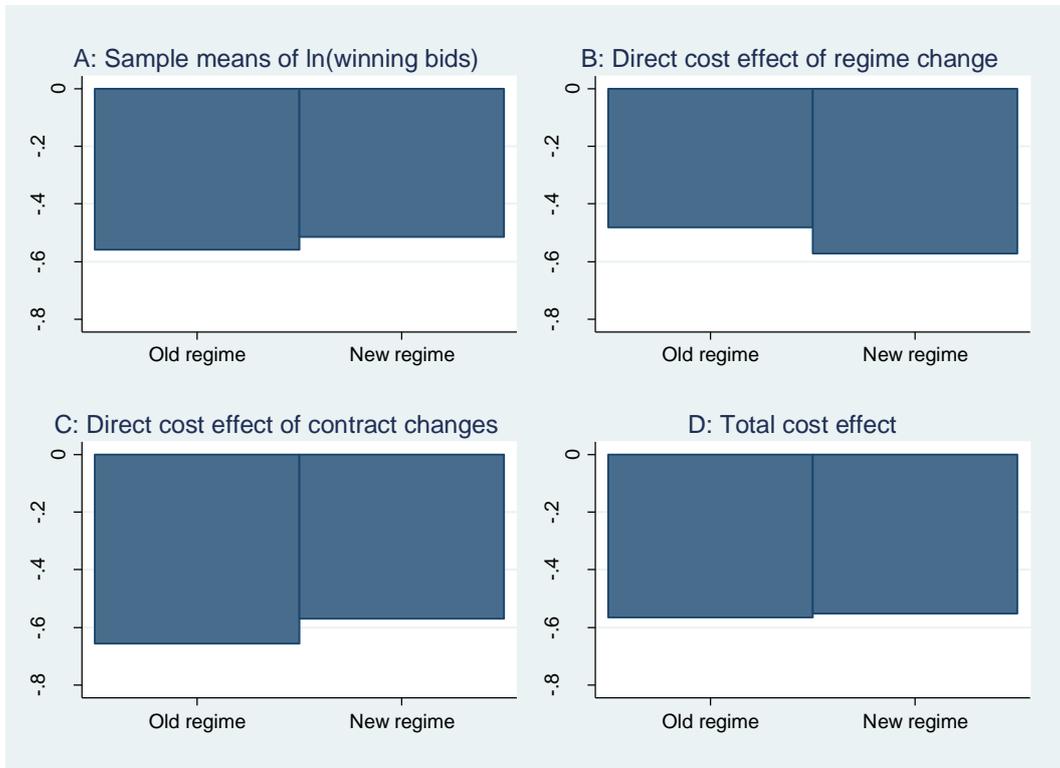

Notes: The standard errors reported in parentheses are bootstrapped (100 replications). *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$. The dependent variables is Ln(bid) and the estimating sample includes all submitted bids.

Figure 1: Entry and its decomposition

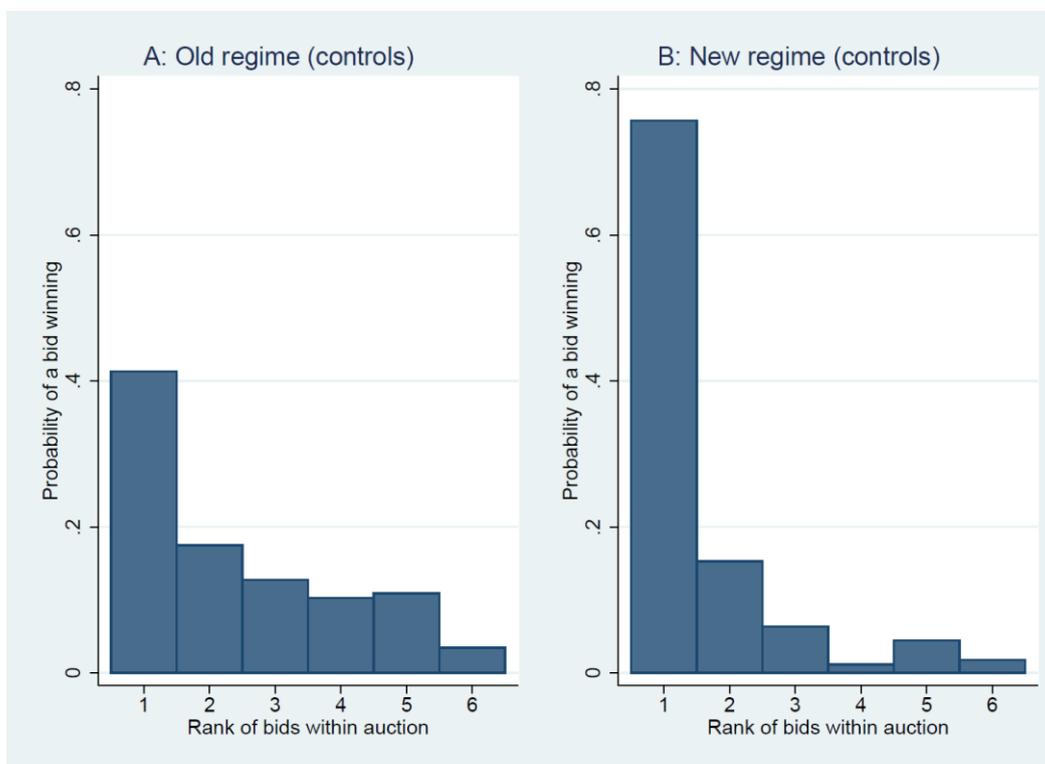

Notes: Actual entry is measured by the logarithm of number of submitted bids, $\ln(n)$. Panel A reports the sample means of the actual entry for the old and new regime. In Panel B-D, $\{X, T, \mu\}$ are set at their overall sample mean calculated over both regimes. Panel B shows how the predicted entry changes when, holding other things constant, the instruments $F = \{Free\ entry, Free\ entry \times R, \ln(N)\}$, and the regime indicator, R , change from the values they obtain in the old regime to their values in the new regime. In Panel B, contract characteristics W are fixed at the sample mean calculated for the new regime. Panel C shows how the predicted entry changes when, holding other things constant, the contract characteristics, W , change from the values they obtain in the old to their values in the new regime. In Panel C, R and F are fixed at their sample means calculated for the new regime. Panel D displays the combined effect of the two effects displayed in Panel B and C. In Panel D, R , F and W assume their subsample values in the old and new regimes, respectively.

Figure 2: Winning bid and its decomposition

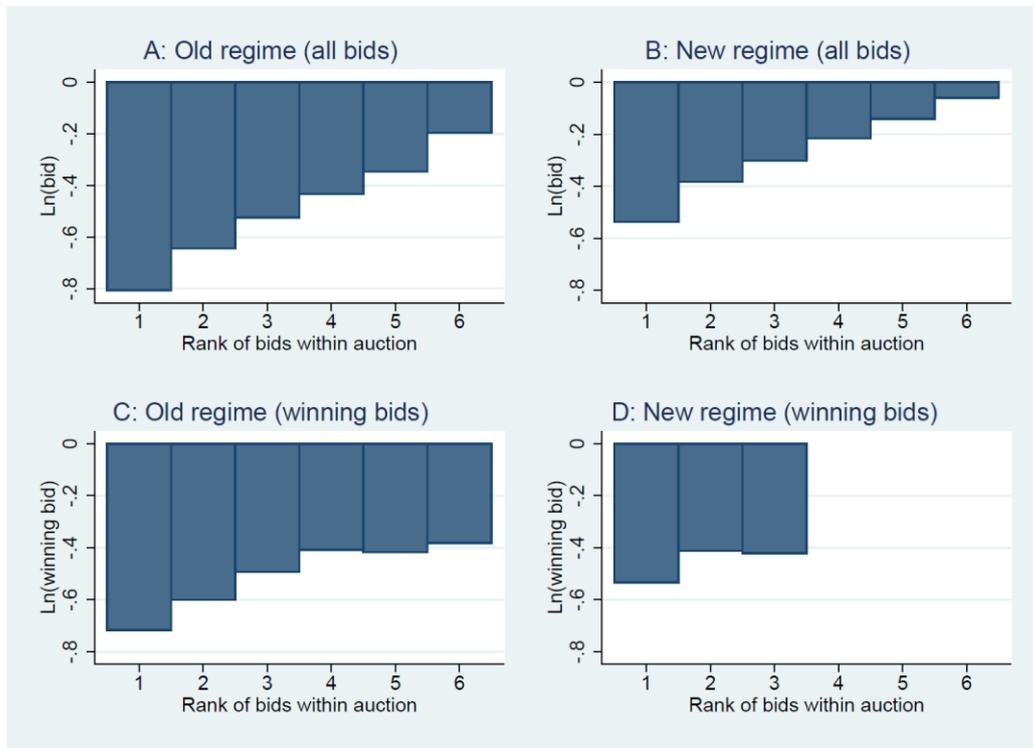

Notes: Winning bid (cost) is measured by the logarithm of winning bid. Panel A reports the sample means of the winning bids for the old and new regime. In Panel B-D, $\{X, T, \mu\}$ are set at their overall sample mean calculated over both regimes. Panel B shows how the predicted winning bid changes when, holding other things constant, the regime indicator, R , changes from the value it obtains in the old regime to its value in the new regime. In Panel B, W and n are fixed at the sample means calculated for the new regime. Panel C shows how the predicted winning bid changes when, holding other things constant, the contract characteristics, W , change from the values they obtain in the old to their values in the new regime. In Panel C, R and n are fixed at their sample means calculated for the new regime. Panel D displays the combined effect of the two effects displayed in Panel B and C. In Panel D, R , W and F assume their subsample values in the old and new regimes, respectively. The effect of F comes through entry only, as predicted by the estimated first stage.

Figure 3: Probability of a bid winning by the rank of the bid

Notes: The x-axis measures the rank of a bid in an auction, based on the monetary component (price) of the bid. The lowest bid obtains the lowest rank. Only the six lowest ranks are displayed, because it was untypical for a winning bid to have a higher rank. The 6th rank includes those few cases in which the winning bid had a higher rank. The y-axis measures the probability of municipalities choosing a bid from a given rank. The figure on the left refers to the old regime and the one on the right to the new regime. The reported probabilities are adjusted for $\{W, X, T, \mu\}$, but the raw probabilities look very similar.

Figure 4: Average bid and average winning bid by the rank of the bids

Notes: The x-axis measures the rank of a bid in an auction, based on the monetary component (price) of the bid. The lowest bid obtains the lowest rank. The y-axis measures the average of the logarithm of the bids in each rank. The reported means are adjusted for $\{W, X, T, \mu\}$. Panel A (old regime) and Panel B (new regime) use data on all submitted bids. Panel C (old regime) and Panel D (new regime) use data on the winning bids. In Panel D, the means of the winning bids are reported only for the three lowest rank categories, because in the new regime, there were only a very small number of winning bids in the higher ranked categories (as can be seen from Panel B of Figure 3).

Endnotes

ⁱ Public procurement amounted to about 12% of the GDP among the OECD member countries in 2013 (OECD, 2015). The EU Commission has estimated that each year, different levels of government spend about 20% of EU's GDP to procure goods, works and services (European Commission, 2012).

ⁱⁱ Using internal records of a bribe-paying firm from an Asian developing country, Tran (2008) finds that mandating the use of auctions curbs corruption only if the procurement auctions are open and if buyers' discretion to pick the winner is limited.

ⁱⁱⁱ Sweden applied the EU procurement law already in the early 1990s and also subsequently. The Swedish rules were relatively lax in the 1990s, because the European rules of that time allowed high degrees of freedom in organizing procurements.

^{iv} Our auxiliary interview evidence suggests that neither improved quality nor increased ex post renegotiations explains this finding.

^v Our IV estimates suggest that the entry elasticity of winning bids is about -0.55, i.e., that when the entry decreases by 10%, procurement costs go up by 5.5%.

^{vi} The municipalities were allowed to freely choose whether to procure or to produce in-house during both regimes. We take in this article as given municipalities' decisions to clean certain premises using procured cleaning services.

^{vii} For example, calls for tender in the new regime included a comprehensive set of mandatory qualification and exclusion criteria and detailed instructions of how the bidders were expected to show that they meet these criteria. However, the service in itself, and the technical specifications remained by and large the same.

^{viii} It is likely that the costs of preparing for and organizing procurement auctions went up in the new regime due to the more detailed mandatory qualification and exclusion criteria and the explicit use of scoring.

^{ix} The available theoretical models do not account for all of these features simultaneously. A structural approach is therefore not likely to be a fruitful direction to proceed.

^x In the first survey, the response rate was 79.5 % and ¼ of the respondents organized at least one procurement auction during 1990-98. >90% of the data of the first survey is from 1995-1998. We have supplemented the survey data with municipality characteristics from Statistics Sweden.

^{xi} The data base is maintained by Visma Commerce AB. This is the largest data base in Sweden and it covers approximately 90 percent of all procurements. It didn't exist at the time of the first survey.

^{xii} In addition to these interviews, one of the authors has had numerous informal discussions with practitioners about Swedish procurement practices.

^{xiii} A typical extension clause means that the contract continues for a specified (extra) period if there were no problems in delivery during the initial contract period. Our data do not allow us to determine which contracts were not extended. Discussions with practitioners suggest that the extension was typically granted.

^{xiv} This means that all auctions in the same size group of a given municipality have the same number of potential bidders. Our results are robust to using the median instead of the 80th percentile as the threshold for large contracts.

^{xv} The bids are expressed in 2013 Swedish krona (1 € ≈ 8.96 krona at the end of 2013). In the regressions where we model bids as outcomes, the dependent variable is the logarithm of the bids.

^{xvi} Many suppliers bid for more than one object in multi-object procurements. Combinatorial bidding was forbidden, thus the winner should have been picked object-by-object. Such choice behavior is a source of inflexibility, e.g., Jehiel and Moldovanu (2001; 2003). We control for the multi-object feature by the number of contracts awarded.

^{xvii} Although not perfect, this is a parsimonious way to capture the main division in Swedish politics, e.g. Aronsson, Lundberg and Wikström (2000).

^{xviii} Our results are robust to excluding T from the model, or to adding its square.

^{xix} Decaloris (2014) argues that a switch to excluding problematic bidders *after* the bids have been submitted may lessen competition among bidders who anticipate being able to later negotiate cost overruns. Although we cannot completely exclude this possibility, such behavior does not appear characterize our data.

^{xx} We would *not* expect a positive coefficient for *Free entry*, if municipalities were more likely to allow free entry into auctions in which *insufficient* entry was expected.

^{xxi} All our results go through if we include potential entry in the 2nd stage of the IV. When we do so, potential entry usually obtains a positive but insignificant coefficient in the 2nd stage.

^{xxii} We replace the *R*-dummy with a (2 x 1) vector of indicator variables for the two auction formats. Having the regime indicator, *R*, in the model is equivalent to restricting the coefficients of the *First price* and *Scoring* -dummies to be equal (leaving *Beauty contest* as the omitted category).

^{xxiii} We cannot estimate such a causal effect because there are no good instruments for the choice of the auction format during the new regime.

^{xxiv} We cluster the standard errors at the procurement level. We have re-run all of these models as count regressions (Poisson models). The results did not change.

^{xxv} In Model 3, we cannot reject the null hypothesis that the coefficient of *Scoring* × *Free entry* is equal that of *First price* × *Free entry* (p-value = 0.47).

^{xxvi} Although large, this difference is not significant at conventional levels (p-value = 0.17). This is mostly due to the larger standard error of the coefficient of *R*. Keeping *R* fixed and changing *F* only, the drop in $\ln(n)$ is -0.29 and the p-value is 0.08.

^{xxvii} In Model 2 and 3, we cannot reject at the 5% significance level the joint null hypothesis that the coefficients of *Scoring* and *First price* are zero (p-values = 0.06 and 0.06, respectively). The coefficient of *First price* is different from *Scoring* in Models 2 and 3 (p-values = 0.02 and 0.02, respectively), but this difference could be due to selection, i.e., due to municipalities using first price auctions for objects for which bidding can be expected to be competitive.

^{xxviii} The difference in the predicted bids is 8.6% (but not statistically significant), i.e., equal to the coefficient of *R* in the second stage (see Table 3, Model 1).

^{xxix} The difference in the height of the bars is 8.4% but is not statistically significant.

^{xxx} This raises the question why the municipalities did not try to induce even more entry. A partial answer is that inducing more entry by adjusting the objects was not without costs. Our second stage estimates reveal the trade-off that the municipalities faced. Holding entry constant, the *direct* effect of making contracts larger and longer was to increase the procurement costs (see Panel C of Figure 2).

^{xxxi} The model allows us to condition out all additively separable effects that are related to observable and unobservable characteristics of the municipals, (un)observable features of the auction format, and to (un)observable contract characteristics. For a detailed explanation of the conditional logit, see Appendix D or Cameron and Trivedi (2005).

^{xxxii} This increase in the price sensitivity is robust across the specifications in the table. We also estimated a model that includes supplier-specific fixed effects, with all suppliers submitting <20 bids grouped into a single category.

^{xxxiii} We ask: by how much should a supplier of type *j* have lowered its bid compared to an inhouse unit to have the same probability of winning, keeping all else the same? We get the answers by dividing the supplier type × *Beauty contest* -coefficient with the Bid × *Beauty contest*-coefficient.

^{xxxiv} E.g., if there were five potential entrants to a large auction and ten potential entrants to a small auction, and if an in-house unit was in both of them, the instrument takes value of 0.2 for the large and 0.1 for the small auctions in that municipality.

^{xxxv} A pseudo first stage of the 2SLS estimation shows that our additional instrument, *S*, predicts *D* well. The t-static of the coefficient of *S* is 5.84 in a regression in which *D* is regressed on the control variables (*W*, *X*, *T*, μ), other instruments (*F*) and *S*.

^{xxxvi} One change was that the municipalities required more proof of quality in the new regime at the bidding stage.

^{xxxvii} In those rare cases they did, our discussions with the industry practitioners suggest that the result seems often to have been a reduction in price, and not additional payments to suppliers.
